## Abstract

**Introduction:** Sentinel lymph node (SLN) mapping with multilevel-sectioning and immunohistochemistry (IHC) or One-Step Nucleic Acid Amplification (OSNA) are considered promising techniques to improve LN staging in colon cancer. This study investigates the prognostic significance of OSNA- and IHC-analysis of ex vivo SNLs of stage I&II colon cancer patients.

**Methods:** 86 stage I&II colon cancer patients were identified from two previously conducted cohort studies. All SLNs were examined with Hematoxylin & Eosin-staining (H&E), multilevel-sectioning with IHC and OSNA analysis. Kaplan-Meier and cox-regression analysis were performed to determine the prognostic significance.

**Results:** Mean disease-free survival (DFS) for OSNA-positive vs OSNA-negative patients was 62.5 vs 62.0 months ( $p=0.886$ ) and for IHC-positive vs IHC-negative patients 58.1 vs 62.9 months ( $p=0.519$ ). Cox-regression analysis showed that positive OSNA-status was not prognostic for DFS (hazard ratio (HR)=0.89,  $p=0.886$ ). Additionally, also positive IHC-status showed no significant difference for DFS (HR 1.47,  $p=0.522$ ).

**Conclusions:** Additional OSNA or IHC-analysis of ex vivo SLNs does not provide a more accurate prognostic value in this small group of stage I&II colon cancer patients compared with conventional H&E. A bigger study is needed to set these results in a broader perspective. Further research is required to identify other clinically relevant upstaging techniques and prognostic factors to tailor the treatment plans of these patients.

## Introduction

Colorectal cancer (CRC) is the third most common cancer worldwide with nearly 1,4 million newly diagnosed patients each year, accounting for 8% of all cancer related deaths [1,2]. In CRC, oncologic surgical resection is the primary therapy, followed by adjuvant chemotherapy on indication. Lymph node (LN) metastasis are one of the most important prognostic factors and are associated with worsened 5-year survival [3]. Previous studies demonstrated that 20-30% of node negative (stage I&II) patients suffer from disease recurrence within 5 years after surgery [4,5]. This could

suggest that current conventional histopathological staging procedures, consisting of one or two sections of Hematoxylin & Eosin (H&E) through each detected LN, may not be precise enough to accurately describe the metastatic load in the resected LNs, possibly leading to undertreatment [6]. More accurate staging techniques are therefore needed to upstage colorectal patients considered to be node negative with conventional H&E examination. In order to improve the detection of LN metastasis, different techniques have been investigated. Sentinel lymph node (SLN) mapping with multilevel-sectioning and immunohistochemistry

(IHC) has been proposed as a promising technique for improved LN staging in patients with colorectal cancer [6,7]. Various studies have demonstrated that the use of either in-vivo or ex-vivo SLN mapping can achieve upstaging rates up to 35% in CRC patients [6, 7]. More recently, the use of One-Step Nucleic Acid Amplification (OSNA) has been trialed in patients with CRC [8-10]. This technique, which is already used in approximately 200 centers as an intra-operative diagnostic tool in breast cancer patients, uses the reverse-transcription loop-mediated isothermal amplification (TR-LAMP) method for mRNA amplification [11]. OSNA determines, within 30 minutes, the metastatic status of a whole LN. In recent years, some groups have investigated OSNA in patients with CRC and described it as a reliable method for improved staging of lymphatic metastases in CRC, with reported upstaging rates of 20-25% [8,9].

The long-term prognostic significance of all these new ultra-staging and upstaging techniques in CRC patients has, until now, not yet been fully investigated. Gaining this information could be important as upstaging and ultra-staging could also lead to overtreatment. Therefore, it is of critical importance to study the long-term value of these techniques. The objective of this study is to investigate the prognostic value of OSNA and IHC in ex vivo detected SLNs of stage I&II (H&E node negative) colon cancer patients.

## Materials and methods

### Patient Selection

For this retrospective follow-up study, patients with stage I&II colon cancer were identified from two previously conducted cohort studies [8]. Patients underwent standard oncological resection between November 2008 and December 2013 at two different centers, Jeroen Bosch hospital (JBH), 's Hertogenbosch and Leiden University Medical Center Leiden (LUMC). Stage III patients, T0 patients and high-risk stage I and II patients that had received adjuvant systemic chemotherapy (i.e pT4 tumor, poorly differentiated histology, presence of lymph vascular invasion, localized perforation and bowel obstruction) were excluded from this study. All other exclusion criteria were reported in the previous study [8].

### Sentinel Lymph Node Mapping Pathological Examination and OSNA-Procedure

SLN mapping was performed ex-vivo within 15 minutes of resection. In patients operated at the JBH, SLN mapping was performed using Patent blue, whereas SLN mapping in the LUMC was performed using indocyanine green (ICG) and near-infrared light. The patent was injected submucosally and circumferentially around the tumor. In both centers the first three colored lymph nodes were marked as SLNs. The SLNs were processed in the same way in both hospitals as previously described [8]. In brief, the SLNs were cut into 4 pieces and labeled a, b, c and d. Slices a and

c were pooled together and analysed using OSNA, and slices b and d were subjected to an intensive multilevel sectioning histologic workup, cut into 4 levels with 250µm between each level, with H&E and immunohistochemistry (anti-Pancytokeratin) [8]. The methods used for OSNA analysis are described in the instrument IFU and reagents package inserts [11,12]. Colon cancer was staged according to the 7th version of the TNM classification system [13]. The SLN's were examined for the presence of tumor cells. All lymph nodes free from metastasis were judged node negative. Sentinel lymph nodes with at least 1 observed tumor cell detected with immunohistochemistry or >250 mRNA copies/µL in the OSNA analysis were judged as positive. A distinction in macro-metastasis [>2mm], micro-metastasis [ $>0.2$  and  $\geq 2$  mm] and isolated tumor cells (ITC) [ $\leq 0.2$ mm] was made for H&E and IHC [14]. Importantly, only results of the conventional H&E staging were used in clinical practice for interdisciplinary tumor board decision making.

### Follow Up

Follow up data were collected retrospectively from the hospital related clinical charts with a median follow up of 50 months. Disease free survival was defined as absence of local or distant metastatic disease diagnosed with the use of computed tomography, MRI or biopsy. Standard follow up examinations were performed using the Dutch oncological follow-up guidelines for colon cancer after curative colon cancer resection [15].

### Statistical Analysis

Statistical analysis was performed using SPSS version 23 (SPSS: An IBM Company, Chicago IL). Continuous variables were compared with the Student's t, Mann-Whitney, one-way ANOVA and Kruskal-Wallis tests, where appropriate. Differences among proportions derived from categorical data were compared using the Fischer's or the Pearson chi-square tests, where appropriate. All p values in the univariate analyses were two-sided and considered statistically significant if  $p \leq 0.05$ . Cumulative survival was calculated with the Kaplan-Meier function and comparison were performed with Log Rank test. The COX regression model was used to identify the adjusted hazard ratio of survival for patients with OSNA and IHC workup. Data are presented as mean (SD), median (IQR), and HR (95% CI) where appropriate.

## Results

### Baseline characteristic

A total of 94 patients were included in the present analysis. Of the conventional H&E negative patients, in four patients there was no tumor present (T0) and to 4 node negative patients featuring high risk factors adjuvant systemic chemotherapy was given who were also excluded. Follow-up was successfully completed in all 86 patients with a median follow up of 50 months (SD:13,31). Baseline characteristics are shown in Table 1.

### Oncological Follow Up

During the follow-up period 16 patients died of whom three patients died due to cancer related progressive disease. In 10 patient's death was not cancer related – in four the cause of death was not further specified, one patient died due to postoperative complications, four due to another malignancy and one patient due to a cerebro-vascular insult. In three patients the cause of death was unknown. Overall, the mean overall survival (OS) was 61.6 months. During the follow-up period 11 of 86 (12.8%) pN0 patients had tumor recurrence. Overall, mean disease-free survival (DFS) was 62.2 months (95%CI= 58.4-66.1months). Distant recurrences were localized in the liver (N= 6), lung (N= 4), skin (N=1) and brain (N=1). Four patients had distant metastasis at two different places at time of diagnosis. Local regional recurrence was localized in lymph nodes (N=3).

### Prognostic Significance of OSNA and IHC in Ex Vivo SLN

A total of 18 patients were node positive by OSNA analysis and 68 OSNA-negative. With the use of multilevel sectioning with

immunohistochemistry (IHC) 30 patients were node positive and 54 IHC-negative. Two patients had missing IHC data. In the IHC node positive patients micro-metastases were found in 2 patients and isolated tumor cells in 28 patients. Recurrence occurred in 2 of OSNA-positive patients vs 9 of OSNA-negative patients and in 5 of IHC-positive patients vs 6 of IHC-negative patients (Table 2). No significant difference in mean DFS for OSNA-positive vs OSNA-negative patients was observed (62.5 months vs 62.0 months (p=0.886)). Also mean DFS for IHC-positive vs IHC-negative patients showed no significant difference (58.1 months vs 62.9 months (p=0.519)). Survival data is shown in Table 3 and figure 1a,b & 2a,b. The prognostic independence of OSNA and IHC was tested with cox regression analysis. A positive-OSNA status was not associated with significant shorter disease-free survival, (Hazard ratio [HR]= 0.89, 95%CI=0.19-4.14, p=0.886). A positive-IHC status was also not associated with significant shorter disease-free survival, (Hazard ratio [HR]= 1.47, 95%CI=0.45-4.83, p=0.522).

**Table 2:** Recurrence characteristics.

<b>Recurrence</b>			
	No	Yes	p-value
<b>OSNA (SLNs)</b>			
Positive	16 (18.6)	2 (2.3)	P= 0.886
Negative	59 (68.6)	9 (10.5)

## Discussion

Our study is one of the first published study investigating the prognostic value for disease free survival of OSNA in the long-term follow-up of ex vivo detected SLNs of a small group of stage I&II colon cancer patients, showing no additional prognostic value. Whilst OSNA analysis and IHC can lead to upstaging of early colon cancer patients as described by Vogelaar et al, positive OSNA or IHC status of the ex vivo detected SNLs were no independent predictors for disease free survival in stage I&II colon cancer patients [8]. Therefore, these new upstaging techniques does not provide a more accurate prognostic value. However, the strength of evidence of these findings might be limited because of the reduced power of this study, since this study consisted of a small group of patients. Therefore, the value of these findings must be proven by a bigger study to set these results in a broader perspective. On the contrary, just recently, Itabashi et al. published a 3-years follow-up study of stage I-III CRC patients with sub-analyses in a small group of 70 stage II patients. Showing a significant worse prognosis for stage II OSNA-positive patients [16]. However, 55% of the OSNA-positive and 22% of the OSNA-negative patients were treated with chemotherapy. Since we corrected for this confounder the results of both studies are not comparable. Furthermore, we believe that our study demonstrates more representative results since chemotherapy influence survival outcome. The above shown discrepancy in OSNA-positive SLNs and SLNs harboring micro metastasis with IHC suggests that the OSNA cut-off value for micro metastasis (> 250-5000 copies of mRNA) is maybe not accurate enough to make a prognostic distinction between positive and negative LN status in stage I&II colon cancer patients [11-17]. New studies in breast cancer patients showed a more accurate cut-off value (> 2500 copies of mRNA) for the detection of micro metastases as a prognostic cut-off value, supporting this suggestion [17,18]. Therefore, it is likely that some LNs harboring ITCs are staged as

positive nodes with the OSNA analysis leading to upstaging without clinical prognostic relevance, which is in line with some previous studies showing the prognostic value of micro metastasis but not of ITCs [4-20]. The strength of evidence of this study might be limited because of the combination of datasets from two different hospitals. However, both hospitals used the same protocol for the work up of the LNs and OSNA analysis. Although the type of marker used to detect the SLNs was different between the two hospitals, previous studies have shown that there is a high correlation between these different makers, and therefore it is very likely that this difference did not affect the detection rates [21]. Besides the OSNA cut-off value, the prognostic value of total tumor load (TTL) is recently investigated in breast cancer patients [22]. TTL is defined as the total number of CK19 mRNA in all OSNA positive SLNs [22]. These studies demonstrated that a TTL of > 15.000 mRNA is a new tool to predict the metastatic involvement of non-sentinel axillary nodes [22]. This new intra-operative tool could be of interest in early colon cancer patients when, in the future, more minimally invasive surgery will be performed. However, this data is not yet available in colon cancer patients and therefore further research is needed.

Furthermore, it is noteworthy that almost all disease recurrences seem to be of haematogenic nature. This metastatic pattern, the knowledge that 20-30% of stage I&II patients suffer from disease recurrence within 5 years after surgery and above mentioned results could suggest that LN assessment has less clinical value in stage I&II CRC patients than expected [4,5]. Another alternative that has been investigated in recent years is the prognostic value of tumor specific histopathological characteristics in these patients. Some of these characteristics of interest are tumor budding, poorly differentiated clusters and peri-neural invasion. Literature regarding these tumor specific histopathological characteristics is not unambiguously, but seems to have prognostic value in defining high risk stage I&II CRC patients [23,24]. Besides histopathological characteristics, several molecular biomarkers for stage I&II CRC patients have been studied in recent years, of which microsatellite instability (MSI) and mutations in the KRAS, BRAF and PIK3CA genes are the most well-known biomarkers [25]. The prognostic value of these biomarkers in stage I&II CRC patients is not yet determined. However, recent studies show that these biomarkers might be valuable in staging I&II CRC patients [25]. Further research is therefore necessary to identify other clinically relevant upstaging techniques or molecular biomarkers and histopathological prognostic factors to improve the treatment of stage I&II CRC patients. In conclusion, this study demonstrated that OSNA-and IHC-analysis of ex vivo detected SLNs does not provide a more accurate prognostic value for disease free survival in a small group of patients with non-metastasized colon cancer compared with the conventional H&E. However, a bigger study is needed to set these results in a broader perspective. Further research is required to identify other clinically relevant

ultra-staging and upstaging techniques or molecular biomarkers and histopathological prognostic factors to identify high risk stage I&II CRC patients, to improve the prognostic assessments and tailor the treatment plans.

## Acknowledgement

The authors thank Sysmex Corporation for technical support and providing study material. M. Hilbink for statistical advice, J. Damen for technical support and B. Weixler for collecting the LUMC follow-up data.

## Statement of Ethics and Funding Sources

The approval of the medical ethics committee of the participating hospitals were described in detail in the previous publication. According to this committees written informed consent was not necessary as this study concerned residual material and there were no treatment consequences. This study was performed according to the code of conduct for responsible use. Sysmex corporation provided the OSNA machine and study material for the OSNA analyses. This source had no role in the preparation of data or the manuscript.
