Abstract

Commonly available dental care and a widespread use of antibiotics in an outpatient setting have not eliminated odontogenic infections which may require inpatient admission as potentially life-threatening conditions. The spread of infection to the deep fascia of the head and neck may lead to severe and life-threatening complications, such as airway obstruction, mediastinitis, sepsis and septic shock, endocarditis or intracranial abscess formation. Clinical presentation of deep fascitis of the head and neck may not correspond to the systemic deterioration in the same patient. Therefore, contrast-enhanced computed tomography should be a standard diagnostic imaging in such cases, as it enables accurate location of inflammation, whereas contrast enhancement enables differentiation between soft tissue inflammation and fluid collections based on their density relative to the one of air. It substantially aids the diagnosis, where the history and clinical presentation are inconclusive. The aim of the paper is to discuss the diagnostic management, presentation and spread of odontogenic infections of the head and neck by presenting the rare case of abscess occupying the left infratemporal fossa and temporoparietal region in a 73-year-old male.

Introduction

General characteristics of head and neck infections

The head and neck infections have their distinct characteristics which differ them from the infections affecting other anatomical locations. It is primarily associated with a complex craniofacial and cervical anatomy, the presence of teeth in the oral cavity, the proximity of paranasal sinuses, abundant blood supply and the presence of vital sensory organs (visual, auditory and olfactory senses) [1,2]. Inflammation develops as a bodily defense mechanism against a noxious agent, which can be either a physical or a biological (e.g. pathogens). The bacterial infection develops as the host immune barrier becomes compromised. This is the key mechanism responsible for head and neck inflammation and infection. Pulp necrosis, periapical periodontitis with abscess formation, infected dental cysts as well as infectious complications of partially or completely impacted teeth are the main source of pathogens in head and neck infections [3,4]. Necrotised pulp of mandibular and maxillary molars, premolars and, less often, single root teeth is the most common site of origin [5-7]. Periodontitis is the aetiologic factor in 20-30% of odontogenic infections [8-10].

The second group of aetiologic factors in head and neck infections are non-odontogenic conditions, including sialadenitis, sinusitis, lymph node abnormalities, and skin infections, such as furunculus (boil). The inflammation can manifest clinically as inflammatory infiltration, abscess and the most severe form of infection, that is, phlegmon of the head and neck. Odontogenic infections are mostly caused by mixed bacterial flora. The most commonly cultured isolates include Streptococcus viridans and Klebsiella pneumoniae [10,11]. As the infection progresses, anaerobic bacteria emerge, which is associated with decreased oxyreductive potential and pH reduction in affected tissues [12-14].

Synthetic penicillin remains the drugs of choice in odontogenic infections of the head and neck, mainly due to its high efficacy, minimum side effects, easy availability and low cost. Second generation cephalosporins, belonging to the class of -lactam antibiotics, are used qualitatively. The main representative of this drug category is cefuroxime, which has a very broad spectrum,
good penetration to the bone tissue, which is vital in treatment of odontogenic infections. It is administered parenterally in its leading pharmaceutical form in an inpatient setting. If anaerobic strain involvement is suspected, metronidazole is a treatment of choice [15-17]. The indications for antibiotic therapy include severe systemic symptoms, extensive local inflammation, immunosuppression, systemic comorbidities (diabetes, RA, liver damage) and upper face or mid-face involvement. Empirical, often combined, treatment should be started immediately and adjusted once the susceptibility testing report is available (usually 72 hours). Cultures and antimicrobial susceptibility testing aim at identifying the causal pathogens, their susceptibility to different antibiotic classes and determining the minimum inhibitory concentration (MIC) needed to inhibit the pathogen growth. The MIC is helpful for determining the effective dosage [18].

**Infection spread within the head and neck**

Spread of head and neck infections may occur in a contiguous fashion, along planes of least resistance from the supporting structures of the affected tooth to fascial spaces of the head and neck. Having crossed the strongest barrier of cortical bone and periosteum, the infection spreads along the adjacent soft tissues [18,19]. The crucial factors which determine the spread of infection include its site of origin (maxilla, mandible), anatomical relationship between the site of origin and muscle insertions/ligaments, alongside the detailed anatomy of craniofacial and cervical fascial layers, spaces and fossae. The fascial space is referred to as the anatomical fascia-lined space, which contains loose connective tissue and additional structures. The fascia is a compact connective tissue membrane, which covers muscles, muscle groups and ensures structural integrity of the body. Its function is complex with protection and regeneration of tissue it surrounds as the key role. A thorough knowledge of the anatomy is essential to understand the passageway of infection and associated clinical signs and symptoms [20,21].

**Case description**

A 73-year old man presented as an emergency at the Department of Maxillofacial Surgery in Wroclaw due to moderately increasing oedema of the left temporal region. He had a history of dental extraction of gangrenous roots of tooth 27 two weeks earlier under local anaesthesia, as well as chronic, treated, hypertension. He reported that 3 days following his extraction, the oedema developed “near his left ear”, which subsequently enlarged yet remained fairly asymptomatic. He did not present with any systemic symptoms such as fever, chills or malaise. The patient reported that he saw his GP about it twice, who recommended cold compresses and non-steroidal anti-inflammatory drugs (NSAIDs). Due to the problems with dental visit, GP issued a referral to hospital treatment to Maxillofacial Department. Clinically, intraoral examination revealed severe dental caries, roots of teeth 13, 23, 32, 42, 46 eligible for extraction and clinically healed dental alveolus of tooth 27 with no signs of inflammation within the left maxilla. An extraoral examination revealed significant head asymmetry. There was a massive oedema stretching from the left subtemporal space, through to the temporal and parietal region (Figures 1a-1c). The oedematous area was medium-soft, fluctuant and slightly tender upon palpation. There was no history of head or craniofacial injury. The patient was verbally responsive and oriented, in a good general condition, with no signs of fever or malaise. He was admitted to the Department of Maxillofacial Surgery as an inpatient for further diagnostic assessments and treatment.
His vital signs at admission were: temperature 36.4°C, blood pressure 140/80 and HR 100’. The patient reported using the following medications: trimetazidine MR 35mg (once a day each morning), atorvastatin 20mg (once a day each morning), ramipril 10mg (twice a day), aspirin 75mg (once a day at bedtime), and bisoprolol 5mg (once a day at bedtime). The WBC count was normal (7.34*10^3/µL, reference range 4-10*10^3/µL), but the C-reactive protein level was elevated (CRP 34.40mg/L, reference range 0-5mg/L). The contrast-enhanced CT of the head was performed immediately. The reported abnormalities included “an irregular area of oedema and inflammatory infiltration within the left masticator space and within the left subtemporal fossa with abscess formation, irregular in outline, sized 2.5 x 8.0cm and small gas collections (…). An extensive abscess and soft tissue phlegmon are present within the cranial integuments, in the left temporoparietal area. The abscess contains gas collections, is 2.7cm thick and 12cm wide (…).

The submandibular lymph nodes and lymph nodes against the carotid vessels on the left are fairly small.” The figures below present contrast-enhanced axial computed tomograms of the head and neck (Figures 2-4) and coronal (frontal) image reconstructions (Figures 5-7). In the light of the above findings, empirical intravenous antibiotic therapy was started, including biocefuroxim 1.5g every 8h, metronidazole 500mg every 8h, fluid replacement therapy (Ringer fluid 1000ml/24h) and pain management. The surgical intervention was performed right after CT scans evaluation and antibiotic delivery. Under a general anesthesia and orotracheal intubation, the two-step procedure was performed. The first step involved a comprehensive dental treatment-extraction of potential inflammatory foci in oral cavity, and the second one - abscess incision and drainage. Having disinfected the skin in the left temporal area, fresh sterile drapes were put in place and the reported purulent fluid collections were incised and drained. Following a manual revision of abscess cavity recesses, a sample for microbial cultures was taken and drains were sutured in place (Figures 8,9). On subsequent days, the patient’s condition improved with decreasing amount of drained contents. On day 3. (72hrs), a negative culture for aerobic bacteria was obtained, followed by a positive culture for anaerobic bacteria on day 6. *Gemella morbillorum* was isolated, resistant to metronidazole and susceptible to amoxicillin and clindamycin. *Gemella morbillorum* is Gram-positive, facultatively anaerobic and non-spore forming coccus. *G. morbillorum* lives as a commensal organism of the mucous membranes of the human oropharynx, gastrointestinal and female genital tracts [21].
The antibiotic treatment was adjusted accordingly replacing metronidazole with clindamycin 600 mg every 12 hrs and leaving biocefuroxim dosage unchanged. The decision was guided by susceptibility test findings and the fact that clindamycin itself has fairly low efficacy against Gram-negative aerobic bacteria [17]. The laboratory tests were repeated 5 days later, with a CRP reduction to 13.37 mg/L. One day later, the follow-up contrast-enhanced CT of the head and neck was performed (Figures 10, 11). The report stated that “the previously reported extensive inflammatory infiltration and soft tissue abscess within the left craniofacial area was incised and drained, subsequently reducing in size (...). The inflammatory lesions within the temporal and subtemporal fossa as well as within the masticator space have also slightly decreased in size”. The patient was hospitalised for 18 days. One day prior to scheduled discharge, the drains were removed and laboratory tests repeated. The findings included CRP reduction to 4.91 mg/L [reference range 0-5.0 mg/L] and almost completely resolved oedema. The patient was discharged home with continued course of antibiotics (clincamycin 600 mg PO twice a day), wound cleaning and dressing change instructions and a follow-up appointment at the Maxillofacial Clinic booked in 7 days.
Discussion

Odontogenic infections still constitute a major group of head and neck infections [2-4]. An infection presenting as local infiltration or abscess may develop secondarily to pathogenic flora presence in necrotic pulp or after any intraoral/ dental procedures involving the alveolar process. The most common procedure is dental extraction, which is always associated with bacteremia. With local and/or systemic vulnerability and risk factors, dental extraction may lead to a local or-very rarely-systemic infection. The treatment of choice in abscesses is a surgical intervention including incision and drainage, in some cases accompanied by medical treatment [6,8,11]. The decision of inpatient admission can be very challenging at times. It should be informed by a thorough history, clinical assessment and diagnostic imaging [12,20]. Any potential life-threatening conditions associated with dysphonia warrant inpatient admission. Similarly, intraoral abscesses, including canine fossa abscesses, should be treated surgically under general anaesthesia. The infection spread in this case via the route typical of maxillary molars, along the subtemporal space, extending through the temporal space, up to the parietal area [10-13]. Effective treatment of odontogenic infections of the head and neck requires accurate diagnosis. It should be noted that the severity of the general condition may not correspond to the clinical presentation, especially with the involvement of parapharyngeal or pterygomandibular spaces [9,13,20]. Contrast-enhanced computed tomography is a diagnostic imaging modality of choice in extensive infections of the head and neck, as it enables precise location of the inflammation, especially with the infection spread to the deep fascia of the head and neck. Contrast-enhanced computed tomography helps to differentiate between the nature of the condition (inflammatory infiltration, abscess, phlegmon) and precisely determines its location, identifying the surgical target [1,16,13]. The abscess occupying the infratemporal, temporal and parietal fossae may also be occurred by trauma or laryngological causes. However odontogenic infections constitute over 49% in head and neck region [1,14,16].
